## **Abstract**

Scavengers existed in the past and they exist now. Often under appreciated.  
Three main habitat types considered: land, air and sea. Different drivers in these  
areas. Review looks at these

# 1 Introduction

2 Historically, scavengers have not been viewed as the most charismatic animals. This may  
3 go some way to explaining the gap in our knowledge of the prevalence of this behaviour.  
4 Prof Sanborn Tenney writing in 1877 for *The American Naturalist* had this to say about  
5 one well known group, “Prominent among the mammalian scavengers are the hyenas, the  
6 ugliest in their general appearance of all the flesh eaters.” He contrasts these with  
7 “nobler kinds” of carnivores such as lions and tigers. However, aside from our own  
8 subjective biases, scavenging is a difficult behaviour to detect after the fact. Without  
9 catching a carnivore in the act of killing we are left to infer how the prey was killed.  
10 Some simple heuristics can inform us, for instance, in cases where the prey item was  
11 simply too large to have been killed by the ostensible predator. But clearly, a scavenger  
12 doesn’t only feed on animals too big for it to have hunted. This is significant, because as  
13 we are now beginning to realise, the extent of this behaviour is enormous among the  
14 carnivores such that, “in some ecosystems, vertebrates have been documented to  
15 assimilate as much as 90% of the available carrion” (Benbow et al. 2015). Even Tenney’s  
16 noble big cats are now known to take in a significant portion of carrion in their diet  
17 where some lion populations get over 50% of their meat from carcasses. The obvious lack  
18 of direct behavioural data compounds the difficulty of discerning scavenging among  
19 extinct forms. Indeed, a single species of dinosaur notwithstanding, a synthesis  
20 describing the natural history of scavengers is absent from the literature.

21 Most if not all carnivorous vertebrates are facultative scavenging behaviour to some  
22 extent. It is recognised that scavengers have an important role in keeping energy flows at  
23 a higher trophic level in food webs than decomposers because they consume relatively  
24 more carrion (DeVault et al. 2003). Scavengers also provide useful ecosystem services by  
25 acting as barriers to the spread of disease by quickly consuming rotting carcasses which

1 have often died from illness (Ogada et al. 2012). Despite this, scavengers are a seriously  
2 understudied group (Sekercioglu 2006, Selva and Fortuna 2007, Wilson and Wolkovich  
3 2011). DeVault et al. (2003) propose that this is due to both human disgust at carrion  
4 itself and the difficulty in determining if an ingested prey item was killed or scavenged.  
5 The latter point means that studying the natural history of this behaviour is particularly  
6 problematic. Indeed, even data on the proportion of carrion in the diet of extant species  
7 are sorely lacking (Benbow et al. 2015).

8 "Indeed, in some ecosystems, vertebrates have been documented to assimilate as  
9 much as 90% of the available carrion"(Benbow et al. 2015).

10 The limitations in studying scavenging in extant species are even bigger in extinct  
11 species and past systems since the obvious lack of available direct behavioural data  
12 (CITE) This means indirect observations in the fossil record and other approaches such  
13 as energetics must be used to infer these behaviours. One avenue to infer scavenging  
14 from palaeontological data can be achieved by determining if a prey item was simply too  
15 big for the carnivore to have tackled in cases where tooth marks are found (Pobiner  
16 2008). Comparative analysis can also allow us to ascertain which morphologies and  
17 physiologies are likely to have been found in scavenging species in the past (Ruxton and  
18 Houston 2004b). The development of indirect measures of scavenging in palaeontology  
19 can in turn be applied to current scavenging systems that also suffer from a lack of  
20 observational data.

21 In this review we collate methods (could this be another way of structuring it, just an  
22 idea) and research from palaeontology relating to scavenging behaviour and show that  
23 ignore this literature would be a missed opportunity for understanding extant  
24 scavenging.

25 Our review is divided up into three sections, namely the land, air and sea. These are  
26 then subdivided into three geological eras the Cenozoic, Mesozoic and Palaeozoic. Each

of these environments has a distinct physical character that affects how a species forages for food which has obvious relevance for an animal searching for carrion. However, there is some commonality to a scavenger's environment and the problems in finding food that one would encounter. Notably, the resource environment of a scavenger is a patchily distributed one, because it is difficult to predict both when and where a carcass is produced. As a result of this, any animal existing as a scavenger must maximise its detection capabilities and minimise its locomotory costs (Ruxton and Houston 2004b). Exploring which groups are likely to have moved towards these traits and thus existed as scavengers over palaeontological time forms the basis of this work. "Interkingdom Competition among Vertebrates, Invertebrates, and Microbes"(Benbow et al. 2015) "For example, vertebrate scavengers appear to be disadvantaged when humidity and temperature favor microbial and invertebrate reproduction" (Benbow et al. 2015)

## 1 Terrestrial Scavengers

As noted above the ease with which natural selection pushes an animal towards the optima of cheap locomotion and large detection capabilities is dependent on the environment the species is in. Land-based scavengers can be thought of as existing in a 2-dimensional plane while foraging for carrion directly. The range at which they can detect carcasses is thus defined by the radius of their sensory organs, usually the visual and olfactory senses.

Large body size confers many advantages to a scavenger. It grants an animal competitive benefits against other species at a carcass, it allows for some resistance to starvation because of greater fat stores and it often means the sensory organs are elevated giving a higher likelihood of discovering food (Farlow 1994).

## 1 **Cenozoic**

2 Among terrestrial African carnivores, hyenas, jackals, lions and leopards all take sizable  
3 proportions of carrion in their diet. In the case of the spotted hyena (*Crocuta crocuta*) it  
4 can be as high as 99% (Benbow et al. 2015). Yet, no contemporary terrestrial vertebrate  
5 exists as an obligate scavenger. The selective pressures that push mammals and reptiles  
6 towards scavenging do not seem to undermine their ability to hunt, perhaps explaining  
7 the absence of obligate scavengers in these groups (Ruxton and Houston 2004b).

8     There is a long running debate on the tendency of human ancestors to scavenge.  
9 Some recent studies have found "that passive scavenging from abandoned larger felid kills  
10 could have been a high-yield, though potentially dangerous, foraging strategy for early  
11 hominins even without considering within-bone nutrients" (Pobiner 2015).

12     Osteophagy is known across a range of terrestrial carnivores. Some fat-rich  
13 mammalian bones have an energy density (6.7 kJ/g) comparable with that of muscle  
14 tissue, making skeletal remains an enticing resource (Brown 1989). Hyenas have a bite  
15 force capable of breaking open bones and early hominins had the ability to craft tools for  
16 this purpose (Hone and Rauhut 2010, Blasco et al. 2014). In light of this, the skeletal  
17 remains of carrion may act as trove of food to carnivores who can access it.

18     Ruxton and Houston (2004b) in a theoretical study suggested that "a 1 tonne  
19 mammal or reptile, in an ecosystem yielding carrion at densities similar to the current  
20 Serengeti, could have met its energy requirements if it could detect carrion over a  
21 distance of the order of 400–500 m."

22     A review by DeVault and Krochmal (2002) found occurrences of scavenging spread  
23 across five families of snakes and states that this behaviour is "far more common than  
24 currently acknowledged."

25     "SAZIMA and Strüssmann (1990) predicted that several components of snake  
26 be-havior contribute to scavenging propensity. They postulated that snakes that rely on

chemosensory information to acquire prey might forage for carrion more frequently than those whose modes of prey acquisition are driven by visual cues. Additionally, SAZIMA and Strüssmann (1990) suggested that habitat and diet preferences might be indicators of scavenging propensity because they influence the likelihood of a particular species encountering carrion naturally. Based on these criteria, they predicted that aquatic or semi-aquatic piscivorous snakes would scavenge more frequently than other species. Moreover, SAZIMA and Strüssmann (1990) suggested that water currents that induce aggregations of carrion heighten the probability of carrion detection by these snakes (see also Savitzky (1992)). Also, chemical gradients may be more uniform and give more dependable directional information in water (SAZIMA and Strüssmann 1990)." (DeVault and Krochmal 2002)

"Investigations of ophidian metabolic requirements unveil additional advantages to carrion utilization. Snakes exhibit exceedingly low maintenance metabolisms, and most can survive on a few scant feedings per year. It is, therefore, possible for snakes to rely largely on infrequent, less energy-rich meals. Carrion, which is by nature ephemeral and unpredictable, may represent such a food source to snakes. Scavenging might allow snakes to meet their low metabolic needs more easily and without the costs associated with subduing prey." (DeVault and Krochmal 2002)

## **Mesozoic**

In a recent publication a modelling approach found that theropods between 27 kg and 1044 kg would have gained a significant energetic advantage over individuals at both the small and large extremes of theropod body mass through their scavenging efficiency. This humped pattern is the result of the disparity between the scaling of energetic cost which scales according to an exponent of 0.91 and energy input that scales according to a cubic polynomial that initially scales according to an exponent of 1.07 but plateaus

1 after 1000kg. The polynomial behaviour of energy input is itself the result of the  
2 limitations imposed by gut capacity and the overall availability of carcasses after  
3 competition.

4 As we discussed for the case of Cenozoic carnivores, osteophagy could be extremely  
5 beneficial to a scavenger. In Mesozoic systems some extremely large theropod dinosaurs  
6 had a morphology which suggests an ability to process bone e.g. the robust skull and  
7 dentition of *Tyrannosaurus rex*. There is direct evidence that *T.rex* did this in the form  
8 of distinctive wear marks on its tooth apices (Farlow and Brinkman 1994, Schubert and  
9 Ungar 2005) and the presence of bone fragments in its coprolites (Chin et al. 1998). The  
10 animal also had an enormous bite force, with one estimate putting it at 57000 Newtons  
11 (Bates and Falkingham 2012). This is noted as being powerful enough to break open  
12 skeletal material (Rayfield et al. 2001). Osteophagy may have been even more viable  
13 during this era because the body mass distribution of herbivores tended to be skewed  
14 towards larger sizes (O’Gorman and Hone 2012). When we couple this with the fact that  
15 skeletal mass scales greater than linearly with body mass (Prange et al. 1979) there  
16 would have been a lot of bones to consume in the environment provided an animal had  
17 the biology to process it.

18 *Allosaurus* tooth marks on a hadrosaur in the Late Jurassic (Chure and Fiorillo  
19 1997). Late Triassic scavenging on a prosauropod by basal carnivorous archosaurs  
20 (Hungerbühler 1998).

22 Synapsids Sprawling gait

## 2 Aerial Scavengers

Species capable of flight have effectively added an extra spatial dimension, i.e. the vertical component, to their sensory environment. This allows them to look down on a landscape where they are unencumbered by obstacles that would obstruct the view of a terrestrial scavenger. Moreover, flight is a cheaper means of locomotion than running (Tucker 1975). Thus, it appears that would-be scavengers have a distinct advantage by taking flight.

### Cenozoic

Birds are the dominant vertebrate fliers today and include the best known scavengers on Earth, the vultures. These birds consist of two convergent groups, old world and new world vultures and represent the only example of obligate vertebrate scavengers. They have a suite of adaptations that allow them to flourish in this niche. Vultures extend the energetic advantage of flight further by engaging in soaring instead of flapping flight, which is even cheaper (Hedenstrom 1993). Their efficiency is illustrated by cases of predators like bears and wolves benefiting by taking more carrion in their diet in areas bereft of vultures through competitive release (DeVault et al. 2003). In flight, birds possess a huge advantage over any terrestrial obligate scavenger. Flight affords them the ability to range over a much larger area and detect carrion from an elevated vantage point. Pennycuik (1972) conservatively estimated that a Gyps vulture could identify activity at a carcass 4 km away.

Many other bird species take a significant amount of carrion in their diet notably the eagles, storks and corvids. Although, none of them are obligate scavengers. By contrast with terrestrial species, the traits that render a bird adept at scavenging do undermine its ability to function as an effective predator (DeVault et al. 2003).

1 The ability to lower BMR at night is reported in some *Gyps* vultures.

## 2 **Mesozoic**

3 In ancient ecosystems, the volant pterosaurs have also been postulated as existing in a  
4 vulture-like niche (Witton and Naish 2008). Certain clades of these animals could reach  
5 enormous sizes (e.g. Azhdarchids) and look to have engaged in soaring flight. However,  
6 the inflexibility of their necks and straight, rather than hooked jaw morphology argues  
7 against their existing as obligate scavengers (Witton and Naish 2008). As yet, no one  
8 has ever attempted an energetics approach for this group which is likely due to the many  
9 uncertainties over their biology (Witton and Habib 2010).

## 10 **Palaeozoic**

11 The absence of flying vertebrates in the Palaeozoic may have permitted terrestrial forms  
12 to take in a higher proportion of carrion in their diet.

## 13 **3 Aquatic Scavengers**

14 The existence of an obligate scavenger in a marine setting also remains hypothetical  
15 (Britton and Morton 1994, Smith and Baco 2003, Ruxton and Houston 2004a, Ruxton  
16 and Bailey 2005). Carrion in this environment is produced by dead flesh and other  
17 marine organisms when their carcasses descend to the sea floor. This low-light  
18 environment means animals detect resources through chemo- and mechanoreception  
19 (Ruxton and Houston 2004a). Detection distances are far lower than they would be in  
20 the air ( $< 100$  m) as a result. However, water is a medium that is conducive to low-cost  
21 movement (Tucker 1975) and so may be able to support a small obligate scavenging fish

(Ruxton and Houston 2004a, Ruxton and Bailey 2005). Although, for the time being this remains conjectural.

"although some benthic scavengers (e.g., hagfish: family Myxinidae) rely on necrophagy for a large portion of their diet and may indeed be obligate scavengers" (Benbow et al. 2015)

## **Cenozoic**

A likely instance of scavenging between a 4-million-year-old white shark (*Carcharodon*) and mysticete whale from Peru (Ehret et al. 2009). Bite marks on early Holocene *Tursiops truncatus* fossils from the North Sea indicate scavenging by rays (Chondrichthyes, Rajidae) (van Netten and Reumer 2009). Possible scavenging on a juvenile fur seal from the Late Neogene (Boessenecker and Perry 2011).

## **Mesozoic**

Evidence of scavenging in a Cretaceous shark species *Squalicorax* whereby remains of a mosasaur and a hadrosaur were discovered with embedded shark teeth (Schwimmer et al. 1997).

## **Palaeozoic**

Evolution of sharks, known scavengers. Evidence of vertebrate scavenging dates back to the early Permian approximately 300 MYA (Reisz and Tsuji 2006).
